Chapter 1

Introduction

1.1 EigenExa and its course of development

EigenExa is a high-performance numerical eigenvalue solver. It traces its history back to EigenES (code name; no formal name) [1] developed on the Earth Simulator, which attained the rank of number one in the world of such systems in 2002. EigenES was nominated for a Gordon Bell Prize at SC 2006 and today continues to serve as an eigenvalue solver on large-scale PC clusters. This led to the initiation of EigenK [2, 3] development around 2008. The EigenK library became the immediate predecessor of EigenExa, and in August 2013 EigenK was renamed EigenExa and public release was begun, following entry into operation on the K computer [4, 5]. EigenExa development continues, with the underlying objective being to achieve an eigenvalue library scalable to operate on future post-petascale (“exa” or “extreme”) computer systems.

In its present release (version 2.3c), EigenExa provides the simplest function of computing all eigenpairs (eigenvalues paired with their respective eigenvectors) for both standard and generalized eigenvalue problems. As reported elsewhere [2, 3], EigenExa applies both classical and advanced algorithms in the same basic manner as EigenK, and thereby reduces the required computation time for diagonalization.

The development of EigenExa includes the utilization of various parallel programming languages and libraries, encompassing MPI, OpenMP, high-performance BLAS, and SIMD vectorized Fortran90 compiler techniques. EigenExa is expected to open the way for high-performance computation through multiple simultaneous functions characterized by the following.

1. Inter-node parallelism in distributed memory architecture, by MPI
2. Parallelism in shared-memory parallel computers and multicore processors, by OpenMP
3. High parallelism utilizing BLAS highly optimized by vendors
4. SIMD or coarse-grained parallelism utilizing vendor-provided high-performance compilers

The good features of Fortran90 are also actively incorporated into EigenExa. The API of EigenExa is more flexible than libraries implemented in Fortran77, and it provides a user-friendly interface, based on modular interfaces and optional parameters. Data distribution is limited to two-dimensional cyclic division, the processor map can be specified in almost any arbitrary configuration, and compatibility and consistency with existing numerical computation libraries are guaranteed if the data redistribution function provided by ScaLAPACK is used. EigenExa also permits user interface specification (or omission) for heightened performance, such as block parameters that strongly affect execution performance.
In the parallel performance of the library itself, it achieves heightened performance by reducing the EigenK communication overhead, and it has been shown that in most cases EigenExa performance exceeds that of EigenK, ScaLAPACK, and others of the highest-level numerical computation libraries [3].

Today, EigenExa is in operation on many HPC platforms, including the K computer and its Fujitsu PRIMEHPC FX10 commercial variant, various cluster computers using Intel x86 series processors, IBM Blue/Gene Q systems, and the NEC vector computer SX series systems. Furthermore, reports on EigenExa have been presented at scientific conferences [6, 7, 8, 9], so if necessary, please refer to them.

This user’s manual for EigenExa version 2.3c covers procedures from installation to actual use, with particular consideration given to installation and compiling, a quick tutorial, the API list, and EigenK compatibility. It is written and provided with the hope of all EigenExa team developers that it will be helpful for achieving efficient parallel simulations by many users.

Chapter 2

Before use

2.1 Software required for EigenExa installation

Several software packages are needed to compile the EigenExa library. BLAS, LAPACK, ScaLAPACK, and MPI must be installed in the system before EigenExa is compiled. To present, it has been confirmed that EigenExa can be compiled with the following libraries.

- **BLAS**
  - Intel MKL, GotoBLAS, OpenBLAS, ATLAS
  - Fujitsu SSL II, IBM ESSL, NEC MathKeisan

- **LAPACK**
  - Version 3.4.0 or later

- **ScaLAPACK**
  - Version 1.8.0 or later

- **MPI**
  - MPICH2 version 1.5 or later, MPICH version 3.0.2 or later
  - OpenMPI version 1.6.4 or later, MPI/SX

2.2 Obtaining EigenExa

All available information on EigenExa can be obtained at the following URL.

Tarball distribution is also performed via this URL. Planning is in progress for provision of further information on EigenExa.

2.3 Compile and install procedure

Several steps are necessary to compile the EigenExa library. Proceed as described in the following installation guideline.

**Decompression and extraction**  First, unpack the tarball on the working directory and then move to the EigenExa-2.3c directory

```
% tar zxvf EigenExa-2.3c.tgz
% cd EigenExa-2.3c
```
Environment setting  Second, edit Makefile and make_inc.xxx to match the user’s environment. For xxx, select and enter the character string corresponding to the compiler to be used, from among the following:

1. BX900
2. Intel or Intel.shared
3. K_FX10 or K_FX10.shared
4. gcc
5. BlueGeneQ
6. SX

The “.shared” suffix is specified in creating a shared library.

make  Third, execute make. This results in creation of the static library libEigenExa.a or the shared library libEigenExa.so.

% make

install  Lastly, copy the library itself, libEigenExa.a (or libEigenExa.so for the shared library), eigen_libs.mod, and eigen_blacs.mod to the install directory, and end the procedure. To install /usr/local/lib, for example,

% cp libEigenExa.a eigen_libs.mod eigen_blacs.mod /usr/local/lib/

generalized eigenvalue computation driver routine  When the generalized eigenvalue driver routine KMATH_EIGEN_GEV with the same number as the installed version is downloaded from

http://www.aics.riken.jp/labs/lpnctrt/KMATH_EIGEN_GEV.html

and followed by make, the KMATH_EIGEN_GEV.o driver module for generalized eigenvalues is created. Linking this object when program linking enables computation of generalized eigenvalues. At present, this function is a higher-level independent module used as the EigenExa eigenvalue computation engine. In this manual, it is described in terms of its relation to EigenExa.
Chapter 3

Quick tutorial

The standard benchmark code can be obtained by moving to the working directory and executing `make benchmark`. The source code components `main2.F` and `Makefile` should be useful for code creation. The kernel of `main2.f` is as follows.

```fortran
main2.f

use MPI
use eigen_libs
...
call MPI_Init_thread( MPI_THREAD_MULTIPLE, i, ierr )
call eigen_init( )

N=10000; mtype=0

call eigen_get_matdims( N, nm, ny )
allocate ( A(nm,ny), Z(nm,ny), w(N) )
call mat_set( N, a, nm, mtype )
call eigen_sx( N, N, a, nm, w, z, nm, m_forward=32, m_backward=128)
deallocate ( A, Z, w )
...
call eigen_free( )
call MPI_Finalize( ierr )
end
```

The above code represents only the framework and does not actually operate, but is sufficient to indicate the overall flow from initialization to sequence assurance to eigenvalue computation to termination procedure.

In the above example, the initialization function `eigen_init()` is executed by a parameter-omitted call. In `eigen_init()`, the group that executes the eigenvalue computation can be specified as a communicator by the form `comm=XXX`. For parallel execution of eigenvalue computation simultaneously by multiple groups, parallel computation is enabled by passing the communicator created by `MPI_Comm_split()`, for example. Note that a constraint exists in the current implementation such that performance of collective operation with respect to the communicator `MPI_COMM_WORLD` within `eigen_init()` requires that `eigen_init()` be called by all processes belonging to `MPI_COMM_WORLD` simultaneously. Since a different communicator can be specified for each individual process, a process not participating in the eigenvalue computation can therefore have `MPI_COMM_NULL` specified for `eigen_init()`, thus having the call skipped for the eigenvalue computation driver `eigen_sx()` itself. In short, it is possible to perform
simultaneous execution of various operations other than `eigen_sx()` processing that include `eigen_sx()`.

In EigenExa, processes belonging to a communicator specified by `eigen_init()` are deployed and used in a two-dimensional process grid. EigenExa is designed to utilize a process grid that is nearly square in shape, to reduce communication traffic to the minimum possible. To heighten user convenience, EigenExa has been developed so that the two-dimensional Cartesian grid adopted by MPI can be specified to `comm`. If the Cartesian shape is two dimensional, then in principle EigenExa can be called and computation performed for any process array, thus enabling execution of complicated parallel processing through combination of the above multi-type communicators. Because the Cartesian process grid is essentially row-major, the Cartesian is prioritized in the event of conflict with an `order='C'` specification. For historical reasons, the default process grid in EigenExa is column-major.

The generation of matrix data is performed in `mat_set()`, which is called just before `eigen_sx()`. The matrix data are distributed on the specified two-dimensional process grid in two-dimensional cyclic division style, and are stored in each process as a local array. Because only some of the data are stored for each process, when matrix elements are accessed, a rule for transformation between global and local indices is required.

The following program is an excerpt from `mat_set()` and is presented to compare the program for generation of a Frank matrix with a global counterloop structure and the same but translated to local counterloops.
! Translated local loop program to compute a Frank matrix
use MPI
use eigen_libs
call eigen_get_procs( nnod, x_nnod, y_nnod )
call eigen_get_id ( inod, x_inod, y_inod )

j_2 = eigen_loop_start( 1, x_nnod, x_inod )
j_3 = eigen_loop_end ( n, x_nnod, x_inod )
i_2 = eigen_loop_start( 1, y_nnod, y_inod )
i_3 = eigen_loop_end ( n, y_nnod, y_inod )
do i_1 = i_2, i_3
   i = eigen_translate_l2g( i_1, y_nnod, y_inod )
do j_1 = j_2, j_3
   j = eigen_translate_l2g( j_1, x_nnod, x_inod )
   a(j_1, i_1) = (n+1-Max(n+1-i,n+1-j))*1.0D+00
end do
end do

The `eigen_loop_start()` and `eigen_loop_end()` are used to transform the loop range. The second and third parameters specify the process number and process ID derived from the communicator, which shows the direction of distribution. In this manual, the correspondence is always [row] → “x” and [column] → “y” (in the case of the communicator for the overall participating process, the “x” and “y” portions are characterless). It is important to note that in EigenExa process IDs are managed as integers, starting with 1. The process ID obtained by the query function `eigen_get_id()` therefore differs from the MPI rank by 1, and the ID must be reduce by 1 in cases where the MPI rank is required.

In the above program, the local loop counter value is translated to the corresponding global counter value to be used, with `eigen_translate_l2g()` used for the this translation. The second and third parameters should be specified in a manner similar to `eigen_loop_start()`, for example. Conversely, to convert the global counter value to the local counter value, `eigen_translate_g2l()` is used, with the proviso that if the global counter value is viewed as a loop value, then `eigen_translate_g2l()` returns the corresponding local counter value on the process that becomes the owner process (the process where the local counter value corresponding with the global counter value is included in the loop). In order to determine the owner process of the specified global loop counter, `eigen_owner_node()` is used. It should be used when broadcasting in reference to a particular row or column vector value.

Furthermore, when progressing to computation together with ScaLAPACK for personnel at advanced levels, the process grid context used by EigenExa should be obtained via the auxiliary function `eigen_get_blacs_context()`, referring to the `mtype=2` portion of the `mat_set()` function (the following shows the kernel of the `PDTRAN()` call that stores the matrix AS transpose in matrix A).
When compiling, in addition to the use of mpi90, it is necessary to set the path (in most cases, the -I option) because of the need to access `eigen.libs` and other modules. To link the EigenExa library, it is also necessary to simultaneously link MPI, OpenMP, ScaLAPACK (if version 1.8 or earlier, then also BLACS), and so forth. In the case of Intel-compiler-based MPI, the procedure is as follows (note that the library names around ScaLAPACK and BLAS vary with the environment).

```
% mpi90 -c a.f -openmp -I/usr/local/include -I/usr/local/lib
% mpi90 -o exe a.o -openmp -L/usr/local/lib -lEigenExa -lscalapack \ 
  -llapack -lblas
```
Chapter 4

API

This section lists the functions in `eigen_libs.mod` that have been assigned a public attribute. The first three routines are the main drivers and the others are utility functions. Parameters having optional attributes attached (written in italics) can be omitted, and can also be specified by TERM=variable or constant value in the Fortran format form.

4.1 eigen_init

Initializes the functions of EigenExa. Process grid mapping can be specified via the parameter `comm` or `order`. This procedure is collective (because collective operation is performed for `MPI_COMM_WORLD` internally in the present version, after which all processes must call this procedure); `comm` can specify a different value for each process group, and when different process groups simultaneously call driver functions (eigen_sx() or eigen_s()), parallel operations are performed in driver function units. If `comm` is `MPI_COMM_NULL`, calling the handlers eigen_sx() and eigen_s() results in an immediate return with no internal action. An inter-communicator cannot be used for `comm`.

```fortran
subroutine eigen_init( comm, order )
    1. integer, optional, intent(IN) :: comm = MPI_COMM_WORLD
       Base communicator.
       Process grid mapping is enabled when a two-dimensional Cartesian grid is
       specified for comm.
       Note: If omitted, then MPI_COMM_WORLD
    2. character(*)*, optional, intent(IN) :: order = 'C'
       Row or Column
       Note: If omitted, then treated as 'C'. If the grid major conflicts
       with the Cartesian comm specification, then 'R' is used.
```

4.2 eigen_free

Terminates EigenExa functions.

```fortran
subroutine eigen_free( flag )
    1. integer, optional, intent(IN) :: flag = 0
       Timer printer flag.
       This parameter is for development, and therefore not ordinarily specified.
       If omitted, then 0.
```
4.3 eigen_get_blacs_context

Returns the ScaLAPACK (BLACS) context corresponding to the process grid information specified by EigenExa.

\[
\text{integer function eigen_get_blacs_context( )}
\]

4.4 eigen_sx

This is the main EigenExa driver routine. Eigenpairs are computed via transformation to a pentadiagonal matrix. This is a collective operation driver; all processes attributed to the process group calling must participate in the call.

\[
\text{subroutine eigen_sx( n, nvec, a, lda, w, z, ldz, m_forward, m_backward, mode )}
\]

1. integer, intent(IN) :: n
   Matrix and vector dimensions
2. integer, intent(IN) :: nvec
   Number of computed eigenvectors
   At present, this option is not supported;
   \text{eigen_sx()} \text{ computes all eigenvectors.}
3. real(8), intent(INOUT) :: a(lda,*)
   Symmetric matrix to be diagonalized
   Array content is destroyed upon subroutine termination but
   the FLOPS count is stored in a(1, 1).
4. integer, intent(IN) :: lda
   Leading dimension of array \text{a}
5. real(8), intent(OUT) :: w(n)
   Eigenvalues in ascending order
6. real(8), intent(OUT) :: z(ldz,*)
   Orthogonal eigenvectors of matrix \text{a}
7. integer, intent(IN) :: ldz
   Leading dimension of array \text{z}
8. integer, optional, intent(IN) :: m_forward = 48
   Householder transformation blocksize (must be even number);
   48 when omitted
9. integer, optional, intent(IN) :: m_backward = 128
   Householder back transformation blocksize; 128 when omitted
10. character, optional, intent(IN) :: mode = 'A'
    'A': all eigenvalues and corresponding eigenvectors (default)
    'N': eigenvalues only
    'X': add to mode A to improve eigenvalue precision

4.5 eigen_s

This is the EigenExa driver routine.
4.6. **eigen_get_version**

Returns the version information of EigenExa.

```fortran
subroutine eigen_get_version( version, data, vcode )
1. integer, intent(OUT) :: version
   Version number in three digits.
The digits indicate major version, minor version, and patch level from the highest.
2. character, intent(OUT) :: date
   Release date.
3. character, intent(OUT) :: vcode
   Code name of the version.
```

4.7 **eigen_show_version**

Print the version information of EigenExa to standard output.

```fortran
subroutine eigen_show_version()
```

4.8 **eigen_get_matdims**

Returns the array size recommended by EigenExa. It is desirable for the user to dynamically allocate the local array using the array dimensions (nx,ny) obtained by this function or a larger
CHAPTER 4. API

numeric value. The overall matrix is (CYCLIC, CYCLIC) divided.

```plaintext
subroutine eigen_get_matdims( n, nx, ny )
1. integer, intent(IN) :: n
   Matrix dimensions
2. integer, intent(OUT) :: nx
   Lower limit of leading dimensions of arrays a and z
3. integer, intent(OUT) :: ny
   Lower limit of second indices of arrays a and z
```

4.9 eigen_memory_internal

This function returns the dynamically allocated internal memory size, while EigenExa is called. The user should ascertain the value returned by this function to ensure avoidance of memory shortage. The type of the return value is changed to `integer(8)` in version 2.3c. If the return value is $-1$ (a negative value), this function warns of possible integer overflow resulting from too large matrix dimension in EigenExa.

```plaintext
integer(8) function eigen_memory_internal( n, lda, ldz, m1, m0 )
1. integer, intent(IN) :: n
   Matrix dimensions
2. integer, intent(IN) :: lda
   Leading dimension of array a
3. integer, intent(IN) :: ldz
   Leading dimension of array z
4. integer, intent(IN) :: m1
   Householder transformation blocksize (must be even number)
5. integer, intent(IN) :: m0
   Householder transformation blocksize
```

4.10 eigen_get_comm

Returns the MPI communicator generated by `eigen_init()`.

```plaintext
subroutine eigen_get_comm( comm, x_comm, y_comm )
1. integer, intent(OUT) :: comm
   Base communicator.
2. integer, intent(OUT) :: x_comm
   Row communicator, attribute of all processes with matching row id.
3. integer, intent(OUT) :: y_comm
   Column communicator, attribute of all processes with matching column id.
```

4.11 eigen_get_procs

Returns information on the number of processes related to the communicator generated by `eigen_init()`.

```plaintext
subroutine eigen_get_procs( procs, x_procs, y_procs )
1. integer, intent(OUT) :: procs
   Number of processes in comm
2. integer, intent(OUT) :: x_procs
   Number of processes in x_comm
3. integer, intent(OUT) :: y_procs
   Number of processes in y_comm
```
4.12 eigen_get_id

Returns information on the process ID related to the communicator generated by eigen_init(). Here, the process ID differs from the MPI rank; it is an integer value starting from 1 in the relation MPI rank = process ID - 1.

```
subroutine eigen_get_id( id, x_id, y_id )
1. integer, intent(OUT) :: id
   Process ID defined by comm
2. integer, intent(OUT) :: x_id
   Process ID defined by x_comm
3. integer, intent(OUT) :: y_id
   Process ID defined by y_comm
```

4.13 eigen_loop_start

Returns the loop starting value in the local loop structure corresponding to the specified global loop starting value.

```
integer function eigen_loop_start( istart, nnod, inod )
1. integer, intent(IN) :: istart
   Global loop starting value
2. integer, intent(IN) :: nnod
   Process number
3. integer, intent(IN) :: inod
   Process ID
```

4.14 eigen_loop_end

Returns the terminal value of the loop in the local loop structure corresponding to the terminal value of the specified global loop.

```
integer function eigen_loop_end( iend, nnod, inod )
1. integer, intent(IN) :: istart
   Global loop terminal value
2. integer, intent(IN) :: nnod
   Process number
3. integer, intent(IN) :: inod
   Process ID
```

4.15 eigen_translate_l2g

```
integer function eigen_translate_l2g( ictr, nnod, inod )
1. integer, intent(IN) :: ictr
   Local counter
2. integer, intent(IN) :: nnod
   Process number
3. integer, intent(IN):: inod
   Process ID
```
4.16 eigen_translate_g2l

integer function eigen_translate_g2l( ictr, nnod, inod )
1. integer, intent(IN) :: ictr
   Global counter
2. integer, intent(IN) :: nnod
   Process number
3. integer, intent(IN) :: inod
   Process ID

4.17 eigen_owner_node

Returns owner process ID corresponding to the specified global loop counter value.

integer function eigen_owner_node( ictr, nnod, inod )
1. integer, intent(IN) :: ictr
   Global loop counter
2. integer, intent(IN) :: nnod
   Process number
3. integer, intent(IN) :: inod
   Process ID

4.18 KMATH_EIGEN_GEV

This is a generalized eigenvalue computing driver routine that uses EigenExa as the eigenvalue computing engine. In this driver, eigen_sx is called to compute the eigenpairs via transformation to a pentadiagonal matrix. The constraints on this driver are similar to those on eigen_sx. Use of this driver routine requires linking KMATH_EIGEN_GEV.o together with EigenExa itself.

subroutine kmath_eigen_gev( n, a, lda, b, ldb, w, z, ldz )
1. integer, intent(IN) :: n
   Matrix and vector dimensions
2. real(8), intent(INOUT) :: a(lda,*)
   Matrix A for computing the pencil \((A - \lambda B)\)
The array content is destroyed upon subroutine termination.
3. integer, intent(IN) :: lda
   Leading dimension of array a
4. real(8), intent(INOUT) :: b(ldb,*)
   Matrix B for computing the pencil \((A - \lambda B)\)
The matrix for transformation to the standard eigenvalue problem is stored upon subroutine termination.
5. integer, intent(IN) :: ldb
   Leading dimension of array b
6. real(8), intent(OUT) :: w(n)
   Eigenvalues in ascending order
7. real(8), intent(OUT) :: z(ldz,*)
   \(B\)-orthogonal eigenvectors of the generalized eigenvalue problem
8. integer, intent(IN) :: ldz
   Leading dimension of array z
Chapter 5

Other key considerations

5.1 Caution regarding compatibility

As the successor to EigenK, EigenExa has inherited many of its functions. Complete compatibility between the two is not guaranteed, however, since their internal implementations differ in certain details. These are mainly differences in function and variable naming rules and in common domain management methods. For the same reason, simultaneous linking of EigenExa and EigenK is not recommended.

5.2 Binding with other languages

The method for calling EigenExa from a language other than Fortran90 is highly dependent on the user’s environment. For further information, refer to “Language bindings” and “Method of linking to multiple programming languages” in the compiler manual. Information of reference may also be found in the “Python binding of EigenExa” project [10], which enabled calling from the Python language.

5.3 Behavior on error occurrence

During initialization, EigenExa checks that it is being executed under appropriate conditions, but error detection is not performed during execution. In some cases, forced library termination may occur if a linked subordinate library such as BLAS or LAPACK produces an error.

Information on bug discoveries is essential for improvement of library quality. On discovery of any bug, please be sure to report it to the developer email address listed on the public website of the library.

5.4 Shared library handling in versions 1.x

Shared libraries were not supported in former versions (1.x), because at the time of their development it was not possible to guarantee complete, collision-free resolution of function names when shared libraries are being used (with certain versions of gcc, abnormal shutdown occurred without resolution of function names at execution). When version 1.x is to be used as a shared library, this must therefore be performed solely at the user’s responsibility.

EigenExa versions 2.x and later are shared-library capable, a development achieved with the technical cooperation of Team Leader Toshiyuki Maeda and other members of the HPC
Usability Research Team at the RIKEN Advanced Institute for Computational Science. As noted in the description of the library build, one should select the appropriate make.inc, and when executing, always remember to make the appropriate settings for the environment variables (such as `LD_LIBRARY_PATH`).
Appendix A

Algorithm overview

A.1 Introduction

Appendix A provides an overview of the eigenvalue computation algorithms used in EigenExa, with the main focus on outlines of algorithms that two driver routines (eigen_s and eigen_sx) use and differences between them. Both routines are designed to meet the underlying EigenExa objective of computing all eigenvalues and eigenvectors of real symmetric dense matrices. For general details about eigenvalue computation algorithms for dense matrices, refer to sources such as [11, 12, 13, 14, 15].

A.2 Various approaches and related projects

Let us begin with a brief introduction to the basic aspects of the eigenvalue computing procedures that is usually applied to real symmetric dense matrices. Textbooks on general matrix computation describe an approach based on tridiagonalization of the input matrix (the green path in Fig. A.1), which is used in ScaLAPACK [16] (and LAPACK). In the first step of this approach (tridiagonalization), however, the performance is limited by memory bandwidth, and therefore is expected to be not sufficiently high on recent computer systems.

This problem led to two development projects, ELPA [17] and DPLASMA [18], which employ an approach based on two-stage tridiagonalization via a banded matrix (the blue path in Fig. A.1). In this tridiagonalization, the dominant cost arises during the first stage, in transformation from dense to band. The byte/flop ratio required in this transformation is smaller...
APPENDIX A. ALGORITHM OVERVIEW

than that in direct tridiagonalization, which means the improvement of effective performance. But the eigenvector back-transformation process also requires two stages (basically doubling the cost). Since high-performance implementation in the first stage of the back-transformation (from \(T\) to \(B\)) is currently difficult, its cost becomes extremely large in obtaining a large number of eigenvectors.

These situations led to the development and provision of two routines for EigenExa. One (eigen\_s) applies an approach based on the conventional (one-stage) tridiagonalization (the green path in Fig. A.1). The other (eigen\_sx) applies an approach in which the eigenvalues and eigenvectors of a banded matrix are computed directly (the red path in Fig. A.1). The following sections describe these two approaches in a little more detail.

A.3 eigen\_s

As noted above, the eigen\_s routine in EigenExa applies an approach based on the conventional (one-stage) tridiagonalization, which is used in ScaLAPACK and other libraries. More specifically, it obtains solutions to the eigenvalue problem \(A x_i = \lambda_i x_i\) \((i = 1, \ldots, N)\) through the following three steps:

1. Tridiagonalization of the input matrix by Householder transformations: \(Q^T A Q \rightarrow T\)
2. Computation of the eigenvalues and eigenvectors of a tridiagonal matrix by the divide-and-conquer method: \(T y_i = \lambda_i y_i\)
3. Back transformation of the eigenvectors: \(Q y_i \rightarrow x_i\)

In step 1, the Householder transformations act from both sides

\[
H_N^{-1} \cdots H_1^{-1} A H_1 \cdots H_N^{-1} \rightarrow T, \quad H_i = I - u_i \beta_i u_i^T
\]

with each column (row) of the input matrix transformed in turn to a tridiagonal matrix (Fig. A.2(a)). Here, we chose the position of the variable \(\beta\) in the equations for its correspondence with the description further below. The computation of the transform by each Householder transformation is usually performed by using the symmetry of \(A\), as

\[
(I - u \beta u^T)^T A(I - u \beta u^T) = A - uv^T - vu^T, \quad v = (w - \frac{1}{2} u \beta (w u^T)) \beta, \quad w = Au. \quad (A.2)
\]

Furthermore, the Dongarra’s method makes it possible to apply a number of transformations to the matrix in the form of matrix-matrix multiplications at a time:

\[
(I - u_K \beta_K u_K^T) \cdots (I - u_1 \beta_1 u_1^T)^T A(I - u_1 \beta_1 u_1^T) \cdots (I - u_K \beta_K u_K^T) = A - UV^T - VU^T. \quad (A.3)
\]

However, matrix-vector multiplications, whose performance is limited by the memory bandwidth, still remain (for obtaining the matrix \(V\)) and is therefore a major bottleneck for high-performance computing.

In the second step, the divide-and-conquer method proposed by Cuppen [19] is applied to compute the eigenvalues and eigenvectors of the tridiagonal matrix. As shown in Fig. A.2(b), a tridiagonal matrix can be decomposed into a block diagonal matrix and a rank one perturbation. The underlying idea of the method is computing the eigenvalue decomposition of the tridiagonal matrix efficiently by using the eigenvalue decomposition of the block diagonal matrix (and recursively apply this idea to the block diagonal matrix).

In the third step, back transformation of the eigenvectors is performed by applying the Householder transformations obtained in the first step to the eigenvectors of the tridiagonal
matrix in the reverse order. Since a number of Householder transformations can be aggregated into a convenient form (compact-WY representation):

\[ H := (I - u_1\beta_1 u_1^\top) \cdots (I - u_K\beta_K u_K^\top) \rightarrow I - USU^\top, \quad U = [u_1 \cdots u_K] \]  \hspace{1cm} (A.4)

at low cost (only for computing a small matrix \( S \)), the back transformation is usually computed via matrix-matrix multiplications (Level-3 BLAS):

\[ H \cdots H_{N-2} Y = (I - U_1S_1U_1^\top) \cdots (I - U_M S_M U_M^\top) Y \rightarrow X, \]  \hspace{1cm} (A.5)

where

\[ Y = [y_1 \cdots y_N], \quad X = [x_1 \cdots x_N]. \]  \hspace{1cm} (A.6)

For this reason, this step is expected to achieve high performance.

![Figure A.2: Schematic of eigenvalue computation by eigen_s.](image)

In eigen_s, the first and third steps are newly implemented from scratch with appropriate thread parallelization, whereas the second step is almost ported from the ScaLAPACK code.

### A.4 eigen_sx

The other driver routine provided in EigenExa, namely eigen_sx, is based on an approach that employs direct computation of the eigenvalues and eigenvectors of a banded matrix. At present, for the reason mentioned in the last section, a pentadiagonal matrix is selected as the banded matrix. More specifically, the eigenvalue problem is solved in the following three steps.

1. **Pentadiagonalization of the input matrix by block version of Householder transformations:**
   \[ \tilde{Q}^\top A \tilde{Q} \rightarrow B \]

2. **Computation of the eigenvalues and eigenvectors of a pentadiagonal matrix by the divide-and-conquer method:**
   \[ B y_i = \lambda_i y_i \]

3. **Back transformation of the eigenvectors:**
   \[ \tilde{Q} y_i \rightarrow x_i \]

In the first step, the block version of Householder transformations are applied to the input matrix from both sides:

\[ \tilde{H}_{N/2-1}^\top \cdots \tilde{H}_1^\top A \tilde{H}_1 \cdots \tilde{H}_{N/2-1} \rightarrow P, \quad \tilde{H}_i = I - \tilde{u}_i\tilde{\beta}_i\tilde{u}_i^\top \]  \hspace{1cm} (A.7)

to transform every two columns (two rows) of the input matrix into a pentadiagonal matrix (Fig. A.3(a)), where

\[ \tilde{u}_i = [u_1^{(i)} \ u_1^{(i)}], \quad \tilde{\beta}_i = \begin{pmatrix} \beta_1^{(i)} \\ \beta_2^{(i)} \\ \beta_2^{(i)} \end{pmatrix} \]  \hspace{1cm} (A.8)

There is no difference excepting the form of \( \tilde{H} \) between Eqs. (A.1) and (A.7), so that the procedure of the pentadiagonalization is the same as the tridiagonalization; the Dongarra’s method can similarly be applied. The performance bottleneck thus resides in the part of computing \( A\tilde{u} \).
In the second step, as shown in Fig. A.3(b), the pentadiagonal matrix is decomposed into
a block diagonal matrix and a rank two perturbation. By treating the rank two perturbation
as two rank one perturbations, we apply the principal of the divide-and-conquer method for
a tridiagonal matrix twice and compute the eigenvalues and eigenvectors of the pentadiagonal
matrix [20].

In the third step, the block version of Householder transformations obtained in the first
step are applied to the eigenvectors of the pentadiagonal matrix in the reverse order, which
is essentially the same as in the case of tridiagonalization. The block version of Householder
transformations can also be aggregated in a form with matrices as in Eq. A.4, and matrix-matrix
multiplication can therefore be used in this step, which promises that this step easily achieves
high performance.

In eigen sx, as in eigen s, steps 1 and 3 are newly implemented with appropriate thread
parallelization, whereas step 2 is a simple extended implementation of the ScALAPACK code
for a pentadiagonal matrix.

A.5 Differences between eigen s and eigen sx

As described in A.3 and A.4, eigen s and eigen sx comprise three similar steps and are nearly
the same in computation procedures. Particularly in the step of the back transformation of the
eigenvectors, there is no essential difference between them. In this section, we mention the main
differences in the first and second steps between them.

Tri/Pentadiagonalization

The essential difference between eigen s and eigen sx in this step is that eigen s processes a
single vector, whereas eigen sx processes two vectors together, e.g.

\[ w = Au \]  
\[ \rightarrow \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} = A \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \]  

(A.9)

In the overall step, the total number of floating-point operations is about the same (at least for
the highest term) for the two routines; amount per operation required in eigen sx is about twice
that in eigen s, but the number of operations in eigen sx is about half that in eigen s because
the former deals with two columns at an operation. For the similar reasons, the amount of the
data transferred among distributed processes is almost the same for the two.

The first difference that becomes evident between the two is in the effective performance
of the floating-point operations (in particular, in matrix-vector multiplications). The data of
matrix \( A \) can be reused when computing \( A \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \), whereas it cannot when computing \( Au \).
This means that the required byte/flop ratio in the former is lower than that in the latter. As a
result, the effect of limitation by memory bandwidth is smaller in the former than in the latter
(theoretically by about half), which indicates the increasing effective performance in eigen sx.

The second difference that becomes evident is in the communication latency, arising from the
difference in communication frequencies. Although the data amount per communication is larger
A.6. CONCLUSION

In eigen\_sx than in eigen\_s, the frequency of communications is lower (by about half). The feature of lower communication frequency (Communication-Avoidance) is a very substantial difference, especially in cases of massively parallel computing, due to the fact that communication latency has become a major problem on recent systems.

In short, eigen\_sx exhibits clear advantages over eigen\_s in terms of both the performance of floating-point operations and the latency cost of communication. In cases where the problem size relative to the number of processes is sufficiently large (with the time for floating-point operations thus dominant), the advantage in effective performance is significant. On the other hand, in cases where the number of processes is large (with communication time thus dominant), the advantage in the latency cost is therefore significant. In total, eigen\_sx is expected to achieve higher performance than eigen\_s.

The divide-and-conquer method

It is clear that eigen\_sx requires more cost (both for floating-point operations and communications) than eigen\_s because the former deals with a rank two perturbation whereas the latter deals with a rank one perturbation. In eigen\_sx, a rank two perturbation is dealt with two rank one perturbations. The computational cost for the first rank one perturbation can be reduced by exploiting the structure of the matrix (i.e. block diagonal), however such benefit done not exist in the computation for the second rank one perturbation; the latter cost is about twice that of the former cost. The resulting cost required in eigen\_sx increases by a factor of about three.

In the divide-and-conquer method, one can reduce the cost substantially by the technique known as “deflation”. The number of opportunities in which deflation can be applied varies with the problem. In addition, it is different even for the same input matrix between routines via tridiagonalization and pentadiagonalization. Therefore, it is not easy to derive a theoretical estimation of the difference between the costs of the two routines.

A.6 Conclusion

In this chapter, we gave an overview of the algorithms employed in the two routines, eigen\_s and eigen\_sx, provided in EigenExa and explained their main differences. Increasing the bandwidth of the banded matrix generally involves the trade-off; it is advantageous in the first step (the transformation step), but disadvantageous in the second step (the divide-and-conquer method). Taking this trade-off into account, we deem that the pentadiagonal matrix is appropriate on today’s systems. With increasing performance of future systems and improved implementation of the divide-and-conquer method (our ScaLAPACK-based implementation seems to be rarely suitable for current systems), banded matrix with larger band width (e.g. heptadiagonal) may prove promising. By contrast, the use of conventional tridiagonalization (eigen\_s) might in some circumstances be the best choice. We hope that an understanding of the information in this appendix will help users to select the routine that is most appropriate to their application.
Acknowledgements

We would like to express our deepest gratitude to all the members of the EigenExa development group for their sincere contribution to developing EigenExa. We also grateful the support from the RIKEN Advanced Institute for Computational Science (AICS). In addition, we appreciate the users of EigenExa for their bug reports and feedback that is beneficial to further quality improvement of EigenExa. Without people and support above mentioned, EigenExa could have not been released.

The EigenExa project has been supported by the following funds.

- MEXT KAKENHI, Grant Numbers 21300013 (FY2012), 23240005 (FY2011–FY2013), and 15H02709 (FY2015–FY2017).

The EigenExa project has used computational resources of the K computer provided by the RIKEN AICS through the following projects.

- HPCI System Research project, project IDs hp140069 (FY2014) and hp140069 (FY2012–FY2013).
- Computational resources for enhancement, Project ID ra000005 (FY2013–).

The EigenK project, the predecessor of the EigenExa project, was supported by the following fund.
